Petersen, DVM, PhD, DABVP (Feline), Jane Sykes, BVSc (Hons), PhD, DACVIM, MBA, Mark E. Westman, BVSc (Hons), PhD, MANZCVS (Animal Welfare), GradCert Ed Stud (Higher Ed)

ABSTRACT

The guidelines are a consensus report on current recommendations for vaccination of cats of any origin, authored by a Task Force of experts. The guidelines are published simultaneously in the Journal of Feline Medicine and Surgery (volume 22, issue 9, pages 813–830, DOI: 10.1177/1098612X20941784) and the Journal of the American Animal Hospital Association (volume 56, issue 4, pages 249–265, DOI: 10.5326/JAAHA-MS-7123). The guidelines assign approved feline vaccines to core (recommended for all cats) and non-core (recommended based on an individualized risk-benefit assessment) categories. Practitioners can develop individualized vaccination protocols consisting of core vaccines and non-core vaccines based on exposure and susceptibility risk as defined by the patient’s life stage, lifestyle, and place of origin and by environmental and epidemiologic factors. An update on feline injection-site sarcomas indicates that occurrence of this sequela remains infrequent and idiosyncratic. Staff education initiatives should enable the veterinary practice team to be proficient in advising clients on proper vaccination practices and compliance. Vaccination is a component of a preventive healthcare plan. The vaccination visit should always include a thorough physical exam and client education dialog that gives the pet owner an understanding of how clinical staff assess disease risk and propose recommendations that help ensure an enduring owner-pet relationship. (J Am Anim Hosp Assoc 2020; 56:249–265. DOI 10.5326/JAAHA-MS-7123)

These guidelines were prepared by a Task Force of experts convened by the American Animal Hospital Association (AAHA) and the American Association of Feline Practitioners (AAFP) and were subjected to a formal peer-review process. This document is intended as a guideline only, not an AAHA or AAFP standard of care. These guidelines and recommendations should not be construed as dictating an exclusive protocol, course of treatment, or procedure. Variations in practice may be warranted based on the needs of the individual patient, resources, and limitations unique to each individual practice setting. Evidence-based support for specific recommendations has been cited whenever possible and appropriate.

Other recommendations are based on practical clinical experience and a consensus of expert opinion. Further research is needed to document some of these recommendations. Because each case is different, veterinarians must base their decisions on the best available scientific evidence in conjunction with their own knowledge and experience.

Introduction

As a medically essential and cost-effective method of infectious disease control, vaccination continues to be a mainstay of feline practice and a critical component of an individualized preventive healthcare plan. These guidelines provide the most current information and recommendations for feline vaccination as determined by a Task Force of experts in feline practice. The recommendations are evidence-guided, based on current peer-reviewed literature and data, and complemented by clinical insights collectively derived from decades of experience. The guidelines update the 2013 AAFP Feline Vaccination Advisory Panel Report and utilize similar recommendations from the 2016 WSAVA [World Small Animal Veterinary Association] Guidelines for the Vaccination of Dogs and Cats.1,2 Both of these previously published resources should still be considered relevant and actionable complements to the 2020 guidelines.

The guidelines continue the established approach of considering inclusion of core (recommended for all cats) and non-core (recommended based on an individualized risk-benefit assessment) vaccines in an individualized protocol. As explained in the guidelines, a patient-specific vaccination plan should consider environmental risk factors and life stage and lifestyle factors that determine the likelihood of infectious disease exposure and susceptibility. For example, not all feline patients originate from a home environment, and conversely, most cats described as "indoor only" might find themselves periodically exposed to other cats. The guidelines discuss other presentation scenarios that can potentially affect a risk-benefit assessment and include updates on feline injection-site sarcomas (FISSs) and other vaccination-related reactions.

A key component of the guidelines are comprehensive, easy-to-reference tables listing approved core and non-core feline vaccines and the relevant considerations for their use. The guidelines are complemented by an online resource center at aaha.org/felinevaccination and supplemental materials at cavets.com/vaccination. The online resources include frequently asked questions about vaccination that clinicians and pet owners raise as well as a vaccine protocol calculator that uses a cat’s life stage and lifestyle information to suggest an appropriate, individualized vaccination protocol.

The guidelines discuss in some detail the importance of staff and client education in implementing vaccination protocols and recommendations for feline patients. This emphasis is noteworthy in view of the fact that many pet owners, especially cat owners, associate professional veterinary care primarily with two events, vaccination and treatment of acute conditions.3 Thus, a healthcare visit for the purposes of vaccination becomes an opportunity to more broadly discuss an overall preventive healthcare strategy with the pet owner. Implicit in this approach is an explanation of how the clinician considers life stage, lifestyle, patient health status, environmental, and epidemiologic factors in making vaccination recommendations. The vaccination event then occurs in the context of a practitioner-client discussion on how preventive healthcare forms the basis for the pet owner to maintain a long, rewarding relationship with the animal in his or her care.

Vaccination Principles

Active immunization, achieved through proper vaccination, plays a critical role in the control of infectious diseases, both for individual cats and for the cat population as a whole. Some vaccines also reduce the potential for spread of zoonotic infections to humans (e.g., rabies). The benefits of routine, widespread vaccination are clear: the incidence of serious disease caused by pathogenic organisms, such as feline panleukopenia virus (FPV), can be reduced dramatically when widespread vaccination is practiced. However, the quality of vaccine-induced immunity is influenced by the patient’s environment, the characteristics of the vaccine, the pathogen, and the patient’s immune competence. Accurate prediction of the outcome of vaccination or the likelihood of exposure to a pathogen is impossible. Therefore, it is important that veterinarians inform cat owners that vaccination is not a guarantee of protection.

In general, kittens are more susceptible to infection and disease than adults. Thus, they represent a primary target population for immunization. As part of a routine wellness program, the vaccination needs of all cats should be assessed annually, in conjunction with a comprehensive physical examination, modifying vaccination and other control recommendations as necessary based on the current risk (see “Vaccination Risk-Benefit Assessment”).

Kittens born to immune queens lack significant transplacentally acquired antibodies4 and instead absorb specific maternally derived antibodies (MDA) through colostrum, which provides important protection during early life. Most absorption occurs within 24 hours of birth. However, this MDA also interferes with active immunization. Serum MDA inhibits immunoglobulin (Ig)G production within the neonate through negative feedback mechanisms. It also neutralizes vaccine antigens and prevents them from stimulating an immune response. MDA then declines at a variable rate. Maternally derived IgG in kittens in one study was lowest at around 3–4 weeks of age, and serum IgG and IgA increased dramatically at 5–7 weeks of age.4 These results suggested that kittens may be susceptible to infectious diseases at about 1 month of age, perhaps as much as 2 weeks earlier than puppies.

Nevertheless, it is critical to recognize that there is considerable individual variation in the rate of decline of MDA, and some kittens maintain high concentrations for months.5 The persistence of MDA is one of the most common reasons for vaccine failure. The amount
of MDA in a kitten at any one time point cannot be predicted because it varies depending on the titer of the dam and the amount of colostrum ingested after birth. As a result, a series of vaccinations is administered to kittens every 2–4 weeks through 16–18 weeks of age in order to increase the chance that successful immunization will occur soon after the decline of MDA to sufficiently low titers. The series is started no sooner than 4 weeks of age, because neonates are more likely to develop vaccine organism–associated disease and may not respond well to vaccination. During administration of the series, a window exists when MDA concentrations are high enough to interfere with immunization but are not sufficient to prevent natural infection. This window of susceptibility can be minimized by decreasing the interval between vaccinations in the series, although use of intervals less than 2 weeks can interfere with successful immunization, especially with attenuated live vaccines.

Once vaccination has been successfully achieved after the decline of MDA, it is generally recommended that a booster vaccine be given 3–4 weeks later (this is especially important for inactivated vaccines, although a boosting effect will also occur following revaccination with attenuated live vaccines). This means that the series must be extended 3–4 weeks beyond the period in which the decline in MDA occurs, with the final vaccination dose being a booster. In the past, it was recommended that revaccination be performed 1 year after the initial kitten series, and then for most vaccines every 3 years thereafter. However, owing to studies that suggest up to one-third of kittens may fail to respond to a final core vaccine at 16 weeks and may have blocking MDA at 20 weeks, the WSAVA recommends that the 1 year vaccine (feline viral rhinotracheitis-calicivirus-panleukopenia only) be replaced with revaccination at 6 months of age.²⁶⁷

In this update, this Task Force has adopted the same recommendation of revaccination against FPV, feline herpesvirus type 1 (FHV-1), and feline calicivirus (FCV) at 6 months of age to potentially reduce the window of susceptibility in kittens with MDA toward the end of the kitten series (16–18 weeks). The Task Force recognizes that this means an additional visit will still be necessary for administration of the annual feline leukemia virus (FeLV) and rabies vaccinations in young cats.

The risk of infection and disease varies with factors such as the age and health of the cat, magnitude of exposure to the infectious agent, the pathogenicity of the agent, and the vaccination history of the cat. Some of the factors that impact an individual animal’s ability to respond to vaccination include interference from MDA, congenital or acquired immunodeficiency, concurrent disease, inadequate nutrition, chronic stress, and very young or old age. Some vaccines (e.g., those for FPV) induce a stronger protective response than others (e.g., those for FHV-1). Because vaccine-induced protection is variable and not absolute, vaccination should not be used as the only form of protection, and other control measures, such as those that reduce exposure to infectious agents, should also be employed.

### Types of Feline Vaccines

Vaccines, including those from different manufacturers that are licensed to protect against the same pathogen, should not be assumed as equivalent. Differences in processes and technology used to produce vaccines, as well as additives such as adjuvants, and vaccine route of administration influence efficacy, safety, and duration of immunity. Vaccines may be inactivated, attenuated live, or recombinant (Table 1). All veterinary vaccines, before licensing, are assessed for efficacy, safety, potency, and purity. Vaccine efficacy is often expressed as preventable fraction, as the proportion of vaccinated animals that do not develop a disease after challenge (so-called sterilizing immunity, e.g., FPV, FeLV, and rabies vaccines), compared with unvaccinated animals that do develop the disease. It can also be expressed as mitigatable fraction (proportion with reduction in severity of clinical signs, e.g., FHV-1 and FCV vaccines). Other claims include reduction of pathogen shedding, prevention of a specific clinical sign, or prevention of mortality. The level or degree of protection claim can therefore be limited.

**Inactivated vaccines** are vaccines in which the target pathogen is “killed” and therefore unable to replicate in the host. Although these vaccines are unable to revert to virulence, they often contain adjuvants and other excipient proteins to promote an adequate immune response, which have been implicated in acute and delayed adverse reactions in cats. Inactivated vaccines produce weaker immune responses of shorter duration when compared with attenuated live vaccines, and more frequent booster immunizations may be required (generally annually). With the exception of rabies, two initial doses of vaccine 3–4 weeks apart in the absence of MDA are absolutely essential to produce an effective immune response, and if more than 6 weeks elapses between these doses, it is recommended in other guidelines reports that the series be repeated.²⁴ Full protection may not develop until 2–3 weeks after the last dose. Inactivated vaccines are generally considered safer than attenuated live vaccines for use during pregnancy and in immunosuppressed animals, although systemic allergic reactions could still jeopardize pregnancy.

**Attenuated live vaccines** (modified live vaccines) contain microorganisms that are artificially manipulated so as to reduce their virulence or are field strains of low virulence. Repeated passage through cell culture is the most common means of attenuation. Because organisms in attenuated live vaccines replicate in the host, they stimulate an immune response that more closely mimics protection from natural infection. There is generally a more rapid onset of immunity than with inactivated vaccines, and, in the
absence of MDA, only one dose of vaccine may be sufficient to provide protection. Partial immunity after vaccination with a single dose of attenuated live FPV vaccines can occur within hours.\textsuperscript{9–11} In addition, live vaccine organisms that are shed can immunize other animals in a population. However, the potential for vaccine organism–induced disease exists. This is most likely to occur in immunosuppressed animals, such as neonates that are younger than 4 weeks old. In addition, use of attenuated live vaccines is more likely to result in the generation of false-positive results as indicated by diagnostic tests that are designed to detect the target pathogen (antigen or nucleic acid). With prolonged shedding of live vaccine organisms, this can be a problem for weeks after vaccination. All bacterial and viral vaccines licensed for intranasal administration in cats are attenuated live, as are a number of parenteral vaccines.

\textit{Recombinant vaccines} are created through manipulation of the deoxyribonucleic acid (DNA) of a pathogen in the laboratory, with reduction in pathogen virulence. Types of recombinant vaccines include subunit, deletion mutant, vectored, and DNA vaccines. Currently, the only available recombinant vaccines for cats in North America are vectored vaccines, which use a recombinant canarypox virus as a vector. In these vaccines, DNA of the pathogen that encodes for an immunogenic antigen is incorporated into the canarypox genome, which then undergoes aborted (limited) replication in the host with expression of the immunogen, in turn inciting a protective immune response. \textbf{Compared with inactivated vaccines, canarypox vectors offer a more rapid onset of immunity and may be more effective in the face of persistent MDA. Canarypox-vectored vaccines also do not require adjuvant and have been associated with a reduced risk of injection-site sarcomas in cats.}\textsuperscript{12} However, one study suggested that the degree of protection induced by the recombinant canarypox FeLV vaccine may not be as robust as that induced by whole inactivated FeLV vaccines,\textsuperscript{13} which might produce sterilizing immunity.\textsuperscript{14} However, moderate to severe immunosuppression

\textbf{Attributes} & \textbf{Inactivated} & \textbf{Attenuated Live} & \textbf{Recombinant} \\
\hline
\textbf{Examples} & FPV, FHV-1, FCV, FeLV, rabies, \textit{Chlamydia} & FPV, FHV-1, FCV, FIP, \textit{Chlamydia}, \textit{Bordetella} & Rabies, FeLV \\
\hline
\textbf{Replication after administration} & Does not replicate & May replicate locally at sites beyond the inoculation site & Limited replication, which is then aborted (for canarypox-vectored vaccines) \\
\hline
\textbf{Initial vaccination in the absence of MDA} & With the exception of rabies, two initial doses required, 3–4 weeks apart & One dose may be sufficient; however, where the likelihood of infection is high, two initial doses are recommended, 3 weeks apart & \textbf{Rabies:} One dose is required. Protective immunity is expected to develop by 28 days \\
& Protective immunity is expected within 7–10 days of the second dose & Protective immunity is expected within 7–10 days of the second dose & \textbf{FeLV:} Two initial doses are required, 3–4 weeks apart. Protective immunity is expected within 7–10 days of the second dose \\
\hline
\textbf{Route(s) of administration as stipulated by the manufacturer} & Parenteral (SC, IM) & Parenteral (SC, IM); FPV, FHV-1, FCV, \textit{Chlamydia} & Parenteral (SC) \\
& & Mucosal (intranasal): FPV, FHV-1, FCV, FIP, \textit{Bordetella} & \\
\hline
\textbf{Adjuvanted} & Yes, with some exceptions & Not required & Some products contain adjuvant; canarypox-vectored products are non-adjuvanted \\
\hline
\textbf{Vaccine organism–induced disease} & Not possible & Possible, but uncommon, following intranasal administration of respiratory virus vaccines or oral exposure to leaked parenteral vaccine on haircoat & Not possible \\
\hline
\end{tabular}
\end{table}
may have impacted the results, so further studies are required to determine whether a clinically important difference exists.

To facilitate vaccine selection, vaccines for dogs and cats have been divided into core vaccines, non-core vaccines, and those generally not recommended. Core vaccines are for all cats with an unknown vaccination history. The targeted diseases cause significant morbidity and mortality and are widely distributed. In general, vaccination for core diseases results in good protection. The Task Force recommends vaccines for FHV-1, FCV, FPV, rabies, and FeLV (cats younger than 1 year old) as core vaccines (Table 2, pet cats; Table 3, shelter-housed cats). Non-core vaccines are optional vaccines that should be considered in the light of exposure risk; that is, based on geographic distribution and the lifestyle of the cat (Table 4). Optional or non-core vaccines for cats include FeLV (for cats older than 1 year), Chlamydia felis, and Bordetella bronchiseptica vaccines.

The not generally recommended category of vaccines pertains to diseases of low clinical significance or that respond readily to treatment; vaccines for which evidence of efficacy in the field is minimal; or vaccines that may produce a relatively higher incidence of adverse events with limited benefit. The Task Force lists the feline infectious peritonitis (FIP) vaccine as not generally recommended (Table 5). This vaccine is labeled for administration from 16 weeks of age, whereas many kittens become infected with coronaviruses well before this age. It also contains a serotype II strain of FIP virus. Serotype I FIP virus strains predominate in the field and do not have cross-reactive neutralizing epitopes with serotype II strains. Therefore, as noted in the previous iteration of these guidelines,1,33 there remains insufficient evidence that this vaccine induces clinically relevant protection in the field.

The decision to vaccinate, even with core vaccines, should be based on a risk-benefit assessment for each cat and for each vaccine antigen. Benefits of vaccination should be balanced against the risk of adverse events, likelihood of exposure, and disease severity. Every effort should be made to ensure that cats are healthy before vaccination. However, concurrent illness (including retroviral infections) does not necessarily preclude vaccination.34 The 2020 AAFP Feline Retrovirus Testing and Management Guidelines state that vaccines should not be avoided in cats with retroviral infection because they can develop more severe clinical disease related to FPV and upper respiratory tract infections after natural exposure compared with uninfected cats.35

### Potential Therapeutic Benefits of Vaccination

Active immunization can enhance non-specific immunity, leading to reduction in disease caused by non-target pathogens. One study showed that vaccination of cats with an intranasal FHV-1-FCV vaccine was associated with reduction in clinical signs following infection.36 More studies are needed to assess the non-target effects of different vaccine types. There is also interest in whether vaccines might provide therapeutic benefits in cats already infected with target pathogens. Improvement in chronic upper respiratory tract signs that were previously refractory to other treatments was documented in 13 cats vaccinated with an intranasal FHV-1-FCV vaccine.35 Most vaccines, however, provide no therapeutic benefit, as clearly documented for FeLV vaccines.36

### Vaccination Risk-Benefit Assessment

#### A Balancing Act

There is always a balance to be struck when considering risks associated with vaccination and benefits of vaccination for the individual patient:

- A decision to vaccinate might involve a young cat residing in a multi-cat household with outdoor access, living in an area with a known high prevalence of the pathogen being vaccinated against.
- A decision not to vaccinate might involve a senior or geriatric cat residing in a single-cat household with no outdoor access, and a vaccine that has poor efficacy against a pathogen with low virulence or limited local prevalence.

The Task Force supports the WSAVA’s recommendation that veterinarians should vaccinate every animal with core vaccines and give non-core vaccines no more frequently than is deemed necessary.3 The decision whether or not to administer a vaccine to a cat, and how frequently, relies on an individual case-by-case assessment by the veterinarian. This involves consideration of the animal, the animal’s environment, and the pathogen in question. Additionally, risk-benefit assessments should consider the safety of the vaccine, other adverse effects of vaccination (e.g., the effect of feline immunodeficiency virus vaccination on in-clinic diagnostic test kits), and the efficacy of the vaccine. The result of this assessment should be an individualized, evidence-guided recommendation to vaccinate or not to vaccinate.

#### Patient’s Characteristics

Age is an important factor in assessing an individual’s risk profile. In contrast to puppies, kittens born to immune queens appear to lack transplacentally acquired antibodies and instead absorb specific MDA through colostrum,4 which provides important protection during early life. Once MDA have waned, however, kittens become susceptible to infection. Most infectious diseases are more prevalent in kittens than adults, and therefore, kittens (in particular, those younger than 6 months old) represent a principal primary target population for vaccination. Conversely, adult cats generally have a more robust adaptive

| Attenuated live | Single dose at intake or where possible at least 1 week before shelter entry; in kittens, the first dose no earlier than 4 weeks, and then q 2 weeks until 15–28 weeks of age | For adults, single dose at intake or where possible at least 1 week before shelter entry | • Vaccination of pregnant queens and kittens ≤ 4 weeks of age should be avoided because of the theoretical concern for cerebellar hypoplasia
• Because of the theoretical risk of clinical signs due to residual virulence of the attenuated virus in an immunocompromised patient, consider avoiding in cats with retrovirus infections
• Provides cross-protection to canine parvovirus
• Considered by many clinicians to be their first choice for protection against FPV, owing to more rapid protective response than inactivated vaccines |
| Inactivated | Not recommended owing to delayed protective response specifically for FPV (see comments in text) | | |
| **Intranasal** |
| Attenuated live | Not recommended in shelters owing to less-than-optimal protection against panleukopenia | | • Do not vaccinate any earlier than 4 weeks of age because of the concern for cerebellar hypoplasia
• Shelters should be aware that postvaccinal clinical signs associated with the use of intranasal vaccines could be confused with those caused by natural infections
• Provides faster protection, which is especially relevant in high-risk populations and with kittens against respiratory disease
• Might cause transient clinical signs of respiratory disease |
| **FHV-1 + FCV** |
| Intranasal | Single dose at intake or where possible at least 1 week before shelter entry; in kittens, administer no earlier than 4 weeks | Single dose at intake or where possible at least 1 week before shelter entry | • Do not vaccinate any earlier than 4 weeks of age because of the concern for cerebellar hypoplasia
• Shelters should be aware that postvaccinal clinical signs associated with the use of intranasal vaccines could be confused with those caused by natural infections
• Provides faster protection, which is especially relevant in high-risk populations and with kittens against respiratory disease
• Might cause transient clinical signs of respiratory disease |
| Recombinant (live canarypox vector) | Two doses 3–4 weeks apart beginning as early as 8 weeks of age | Two doses 3–4 weeks apart | • Optional in individually housed cats but shelters should consider the benefits of vaccinating more cats against FeLV
• Strongly recommended in group-housed cats
• Recommend testing to establish FeLV antigen status prior to vaccination (see text for comments)
• There is conflicting evidence in the literature regarding efficacy and safety when comparing recombinant and inactivated vaccines (see text for comments) |
| Inactivated | Administration instructions | | |
| **FeLV** |
| Parenteral | Follow vaccine label instructions and local laws | | • Necessary for all cats where legally allowed/mandated or in an endemic region
• The authority to administer rabies vaccine to shelter-housed cats is often stipulated by state or local law and may not be at the discretion of shelter personnel
• In states/provinces where rabies vaccination may not be mandated, shelters should consider the benefits of vaccinating more cats against rabies
• There is conflicting evidence in the literature regarding efficacy and safety when comparing recombinant and inactivated vaccines (see text for comments) |
immune response when challenged (assuming they are healthy and not immunocompromised), whether due to previous natural exposure or vaccination, and age-related resistance to challenge is particularly a feature of FeLV infection. Consequently, vaccination of mature cats is generally considered less critical than vaccination of kittens. The presence of concurrent disease or stress causing immunosuppression should also be a consideration prior to vaccination because this may affect an animal’s susceptibility to infection and response to vaccination.

Patient’s Environment
Population density and opportunity for exposure to infectious agents are two critical issues that should form part of the risk-benefit assessment. In general, cats and kittens living in larger multi-cat households and environments (e.g., boarding, breeding, foster, or shelter facilities) have a higher risk of infection than cats living in one- or two-cat households. In addition to the possible presence of infected animals acting as reservoirs for infection in multi-cat households, the immunosuppressive effects of stress associated with high-density feline housing may result in reactivation of some infections as well as increased susceptibility to new infections. The introduction of new cats into multi-cat households also increases the risk of infectious disease not only to the cat entering the household but also to the whole group because of possible direct exposure to new infectious agents.

When assessing the opportunity for exposure to a given pathogen for an individual cat, the lifestyle of the cat and other cats in the same household needs to be considered. It is critical to determine whether the cat is indoor-only or has outdoor access (including supervised outdoor visits on a harness, or boarding) because cats with outdoor access may be at increased risk of pathogen exposure. Indoor-only cats, however, may still be determined to be at risk of exposure to pathogens, either from other cats in the household (i.e., subclinically infected or carrier cats), or by fomite transmission of pathogens brought in from outside on the owner’s body, clothing, or shoes. Indoor-only cats may also be exposed to infectious agents when brought to a veterinary clinic for a wellness examination. In theory, strictly indoor cats may be more susceptible to developing some infectious diseases (such as FPV and FCV infection) than cats with outdoor access because they may not receive “natural boosting of immunity” that occurs with natural exposure.

The geographic distribution of infectious agents may also result in different risks of exposure (e.g., rabies), and therefore, questions regarding future travel should be included in determining the risk of exposure to specific infectious agents.

Infectious Agents

The likelihood of infection and disease is influenced by pathogen factors such as virulence, strain variation, and challenge dose (i.e., how many infectious units of exposure). The need for vaccination is greatest against pathogens with high virulence, such as FPV, and pathogens that cause widespread morbidity, such as FHV-1.

Creating an Individualized, Lifestyle-Based Vaccination Plan

The vaccination needs of each cat should be evaluated individually and rationally, based on health status, age, and possible, realistic exposure to disease (Table 6). Owners and veterinarians must work together to determine the likelihood of the animal coming into contact with other animals that may spread disease, acquiring parasites that may harbor a disease-causing agent, or living in an area where a disease is known to be endemic or very widespread.2

Questions must be asked about the lifestyle of that specific cat as well as any other cats in the household or potentially introduced into the household. The travel, boarding, housing, and enrichment activities or excursions outside of the home should also be considered.1 This risk assessment for exposure to disease should be done at least once a year.

The life stage of the cat must also be considered with respect to possibility of exposure to disease and the health status of the animal. Infectious diseases are more prevalent in kittens, and in general, kittens (younger than 6 months old) are more susceptible to infection.1 Younger cats also tend to behave more unpredictably and require more enrichment activities, which may increase their opportunity for exposure.37

The health status of the individual cat, including any previously documented adverse events to vaccines, also determines the vaccination recommendations. The nutritional status, general health (i.e., any concurrent infections or other disease) and the pregnancy status of females may change the type and schedule of vaccination for that individual cat (Table 6). As with lifestyle changes, changes in health status must be evaluated at least yearly.1

The population density, along with the opportunity for exposure to other cats, is a major factor in determining the need for vaccination. Larger multi-cat households are likely to have a greater risk of infection and disease than households of one or two cats. The introduction of new cats and the social dynamics of the group may also cause immunosuppressive stress, leading to increased risk of disease by new infection or recrudescence. Each cat in a multi-cat environment must have a vaccination plan that balances the protection of the individual with that of the household population.1

Cats entering boarding, breeding, foster, or shelter situations have increased risk of disease exposure as well as systemic stress. Vaccination may be warranted prior to entering these environments when possible (see Tables 2 and 3). Additionally, vaccination intervals may need to be shortened depending upon these possible scenarios.1 As with multi-cat households, the vaccination plan for the individual cat must be considered in relation to the entire population.

One vaccination plan or protocol cannot be applied to every cat. Each animal must be evaluated and an individualized plan created that will most protect that particular cat. That plan must be reassessed when changes in health and lifestyle occur, requiring client education and compliance with at least yearly veterinary visits.38

Feline Patient Populations

For the purpose of creating specific, individualized vaccination recommendations based on risk of exposure, the Task Force has identified and defined the following feline populations based on their environment and lifestyle. The guidelines begin by discussing pet cats and then discuss a number of feline populations that are considered to be at relatively high risk of infectious disease exposure—namely, shelter cats, trap-neuter-return/trap-neuter-release cats, cattery cats, and foster cats.

Pet Cats

Pet cats include any cat kept by human beings as a source of companionship and pleasure. Pet cats are further categorized by

housing status (indoor, outdoor, or indoor-outdoor cats) and number of cats in the household (single-cat or larger multi-cat). Although these distinctions are important, the most significant issue to consider regarding vaccination of pet cats is the individual cat’s exposure risk and exposure frequency to other cats and feline infectious diseases. Even indoor cats from single-cat households will inevitably be exposed to other feline infectious pathogens in situations such as a veterinary clinic visit, contact with other cats entering the premises, or exposure to contaminated fomites introduced by human contact. Client education for owners of these patients should focus on risk of exposure to other cats rather than on where the cat eats, sleeps, or spends most of its time.

For high-risk, multi-cat households, the probability of infectious disease exposure and transmission is proportionate to the number or density of cats on the premises. It is important to educate clients about the increased disease risks to this population of cats and to discuss increased owner responsibility to ensure appropriate preventive healthcare initiatives associated with housing many cats in a confined space.

Shelter Cats
These are cats living for indeterminate periods in centers for relinquished or lost animals.

Trap-Neuter-Return/Trap-Neuter-Release Cats
These are community or feral cats of either sex that live entirely separate from people and cannot safely be handled. Trap-neuter-release/trap-neuter-return cats may survive completely independently of humans, but some semiferal colonies receive support from individuals.

Cattery Cats
These cats are maintained in commercial facilities; for example, breeding or boarding facilities, and pet stores with a showcase model.

Foster Cats
Foster cats are kittens or adult cats temporarily housed for rescue, rehabilitation, and rehoming purposes. The most important consideration in a foster cat household is ensuring that the permanent population of the household is appropriately vaccinated to provide protection from disease exposure originating with foster cats.

Serology and Diagnostics
The interpretation of an antibody test result can be complex because antibody testing is used for many reasons. Depending on the antibodies tested for, antibody testing can be used for (1) diagnosis of infection, (2) identification of previous exposure to pathogens (particularly in unvaccinated animals), and (3) assessment of immunity prior to or following vaccination (Table 7). Clinicians should understand when and why to perform antibody testing and use this knowledge to make evidence-based decisions prior to vaccination.

Hemagglutination inhibition (for FPV) and serum neutralization (for FHV-1, FCV, and rabies) are the reference standards to determine the presence of effective antibody-mediated immunity. These test methodologies can only be performed in a laboratory setting using live cell cultures (i.e., they cannot be performed in a practice using rapid patient-side test kits). These diagnostic tests are predominantly research tools used in vaccine efficacy and prevalence studies.

It is important when attempting to demonstrate protective immunity in a patient using an in-clinic antibody test kit that the performance of the kit be compared against the appropriate reference standard in order to demonstrate correlation with protective immunity.

The presence of anti-FPV antibodies correlates strongly with protection (Table 7). Currently, experts recommend antibody testing for FPV to assess immunity and inform decisions about whether to vaccinate. Rapid in-clinic test kits to detect antibodies to FPV, FHV-1, and FCV are available to veterinarians in North America and have been validated in two different studies using the appropriate reference tests. Of concern, however, was the occurrence of some anti-FPV antibody false-positive results in one study, which in practice would lead to some unprotected cats not being vaccinated.

Adverse Postvaccination Reactions
Although the administration of biological products is never entirely free of risk, currently available feline vaccines have an excellent safety record. That said, the true prevalence of adverse reactions is likely to be underestimated owing to underreporting by both veterinarians and owners. Therefore, it is important to report any known or suspected negative events associated with vaccination. In the United States, veterinarians are requested to contact the manufacturer (Veterinary Technical Services) of the vaccine(s) considered to be involved. Veterinarians may also report known or suspected adverse events directly to the U.S. Department of Agriculture; the Center for Veterinary Biologics of the U.S. Department of Agriculture’s Animal and Plant Health Inspection Service can be contacted by the following means:

- Website: https://www.aphis.usda.gov/aphis/ourfocus/animalhealth/veterinary-biologics/adverse-event-reporting/CT_Vb_adverse_event
- Mail: Send the report form to the Center for Veterinary Biologics, 1920 Dayton Avenue, PO Box 844, Ames, Iowa 50010
- Telephone: (800) 752-6255.

At the time of vaccine administration, included in the patient’s permanent medical record should be the name, serial number, expiration date and manufacturer of the vaccine(s) given, date of administration, name of the person administering the vaccine(s), and the site and route of the vaccine administration. Adverse events
Prevalence and Types of Adverse Reactions

Postvaccination adverse events in cats are considered rare. In the most substantial survey to date, any adverse reactions were recorded for cats presented to Banfield Pet Hospitals in the United States between 2002 and 2005. During this period, more than 1.25 million doses of various vaccines were administered to nearly 500,000 cats. Adverse reactions within 30 days of vaccination were reported at a rate of 0.52% of cats vaccinated. The most commonly reported vaccine reactions are lethargy, anorexia, and fever for a few days after vaccination, or local inflammation at the site of injection. In the Banfield Pet Hospital population, the risk of an adverse reaction was greatest in cats around 1 year of age and/or increased as the total volume of vaccine and number of vaccines administered concurrently increased.

Hypersensitivity Reactions

Although anaphylaxis (type I hypersensitivity reaction) is rare (approximately 1–5 per 10,000 vaccinations), it may manifest as vomiting, diarrhea, respiratory distress, facial or generalized pruritus, facial swelling, and collapse. Where revaccination is considered necessary in a cat that has experienced an allergic reaction, using a different vaccine formulation and premedicating with an antihistamine and glucocorticoid 20–30 minutes prior to vaccine administration is recommended, followed by close observation of the patient for several hours. Other forms of hypersensitivity reactions (types II, III, and IV) almost certainly also occur in cats after vaccination, but these are rarely documented.

Postvaccination Monitoring

The Task Force recommends that veterinarians and owners monitor the vaccination site for swelling or lumps using the “3-2-1” rule. Biopsy of any mass present is warranted if it (1) remains present 3 months after vaccination, (2) is larger than 2 cm in diameter, or (3) is increasing in size 1 month after vaccination. It is recommended to obtain an incisional biopsy on any masses meeting any of these criteria. FINE-needle aspirates may not provide diagnostic cellular tissue, whereas excisional biopsies rarely meet appropriate margins (5 cm in two fascial planes) as required in the case of injection-site sarcomas, thus increasing the morbidity and mortality risks associated with sarcoma invasion.

Update on Feline Injection-Site Sarcomas

FISSs, largely caused by vaccines (although other materials have been implicated), have been recognized since 1991. Three decades later, much about them remains unknown. Within the United States, FISS

</table>
Although low, incidence estimates have varied by at least an order of magnitude, and worldwide FISS incidence estimates vary by country depending on the use of vaccine types (e.g., FeLV, rabies) and population susceptibility.

The Task Force makes the following observations regarding vaccination:

- Neither vaccinating in the interscapular space nor decreasing vaccine volume is recommended.
- Distal limb injection is recommended to facilitate amputation with 5 cm margins in two fascial planes in the case of injection-site sarcoma (Figure 1).
- More recently, ventral abdominal subcutaneous injections have been used because of the perceived relative ease of tumor removal without the need for amputation. However, the need to remove two fascial planes and 5 cm margins would still necessitate aggressive tissue removal from the abdomen and abdominal cavity.
- Tail vaccination has also been reported as well tolerated and elicited acceptable serological responses to vaccination in the distal limbs. Tail vaccination must be administered in the distal tail, something that may not be practical for most clinicians.
- Follow the 3-2-1 rule for postvaccination swelling. Obtain incisional biopsies for appropriate diagnosis.

Experimental studies of vaccine-induced inflammation: These studies provide weak evidence for detecting differential vaccination effects on sarcoma incidence yet represent progenitors of the “more vaccine-induced inflammation leads to increased sarcoma risk” conjecture. One immediate problem is that it is unclear how to define inflammation in the context of tumor induction. Macy and Hendrick (1996) cite an unpublished study that defined inflammation as “the size of the local reaction.” Grosenbaugh et al. (2004) interpreted it as the presence of “injection-site reaction,” which could have included “scab, crust, swelling, erosion, ulceration, or pain at the injection site or development of lameness.” Day et al. (2007) used histopathological scoring that included quantifying neutrophils, lymphocytes, and macrophages (inflammatory phase of tissue reaction); quantifying fibroblasts, collagen, and granulation tissue (repair phase); and assigning a “global severity score” based on biopsy site reactivity and extension of involvement of the tissue section. Because the many manifestations of inflammation in cats do not invariably lead to neoplasia, more sensitive biomarkers such as DNA damage may one day be used to distinguish the potential for adjuvanted versus non-adjuvanted vaccines to induce tumors. But because none of the cats in the above studies developed sarcomas, such experimental research does not have logical standing to infer relative vaccine safety.

Associational studies of diagnoses: In the past 10 years, two studies based on data from pathology registries have provided contradictory findings. Wilcock et al. (2012) found no decrease in the proportion of “post-vaccinal sarcomas” in feline skin and subcutaneous mass submissions from 1992 to 2010 in a Canadian registry despite the introduction of a non-adjuvanted rabies vaccine in 2000. In contrast, Graf et al. (2018) studied the proportion of feline biopsies that were
fibrosarcomas submitted to Swiss pathology laboratories between 2009 and 2014 and noted “a marked drop in the relative frequency of fibrosarcoma diagnoses after the introduction of a non-adjuvanted FeLV vaccine into the Swiss market” in 2007 (rabies vaccines are rarely used now in Switzerland). Such studies of diagnostic proportions are difficult to interpret. Moreover, they are influenced not only by disease incidence but also by factors related to differential cost and motivation for histopathologic diagnoses, which are subject to change over time. Therefore, there are always competing explanations for findings.

Longitudinal studies of comparative incidence: A study by Srivastav et al. (2012) is the only one to perform a comparative (case-control) analysis of vaccine types in common use in the past 10 years. Unlike previous epidemiologic studies, it provides tenuous evidence that non-adjuvanted vaccines may be less likely to induce sarcomas than adjuvanted vaccines. However, the work suffers from sample size limitations and bias concerns. Although it arguably serves as an epidemiologic-methods blueprint for future investigations, it is insufficient to justify a wholesale recommendation for a single vaccine formulation with as yet unforeseen consequences on population immunity. The Task Force believes that there is currently insufficient research to justify recommending a single vaccine type. Since injection site sarcomas are a risk, the Task Force recommends vaccination in the lower distal limbs to facilitate clean margins if surgical amputation is required.

Frequently Asked Questions
A summary of frequently asked questions is available online at aaha.org/felinevaccination and catvets.com/vaccination.

Staff and Client Education
The Veterinarian’s Role and Responsibilities

- A veterinarian should assess every patient regardless of appointment type (wellness, acute care or follow-up visit) for current vaccination status based on age and lifestyle. Informed by this assessment, an individualized patient vaccination plan should be developed or modified and then discussed and agreed upon in collaboration with the cat owner.

- In addition to overseeing the development of feline vaccination protocols, the veterinarian should provide staff education on the following:
  - Zoonotic disease prevention.
  - Separate administration sites for each vaccination (based on consistent vaccination site guidelines for that practice).
  - Potential life-threatening adverse events (i.e., anaphylaxis) and minor adverse events (i.e., localized swelling) following vaccination.
  - Vaccine reconstitution and handling (the AAFP recommends using vaccines within 30 minutes of reconstitution).
  - Standard sharps safety procedures to prevent accidental needle sticks.

The Centers for Disease Control and Prevention (CDC) online training module, “You Call the Shots: Vaccine Storage and Handling,” is a useful resource for staff training on vaccination. The practice should designate a person to be the primary vaccine coordinator for the facility. This person will be responsible for ensuring all vaccines are stored and handled correctly. A second staff member to serve as an alternate in the absence of the primary coordinator should be appointed (this is particularly important in case of after-hours emergencies). Both coordinators should be fully trained in routine and emergency policies and procedures.

The healthcare team, led by the veterinarian, should emphasize and educate clients that they are part of a team approach to vaccine management, requiring the entire staff’s understanding of zoonotic disease, core and non-core vaccines determined by the pet’s lifestyle, hospital policy, state law, client compliance, and adverse vaccination events.

Credentialed Veterinary Technician or Veterinary Assistant Roles and Responsibilities
A veterinary technician or assistant often assumes the role of designated vaccine coordinator, assisting in vaccination storage and inventory management. AAHA guidelines on vaccine storage and handling, and the CDC Vaccine Storage and Handling Toolkit are useful resources for this purpose. The vaccine coordinator is often responsible for reconstitution of vaccines and administration of vaccinations as directed by the attending veterinarian in compliance with state law. This individual is also often given responsibility for implementing feline-friendly handling techniques in the hospital setting to minimize stress during examinations and vaccine administration and for maintaining effective client education and follow-up, including verbal and written instructions on potential adverse events after vaccine administration and disease prevention.

Roles and Responsibilities of Reception and Other Client-Service Personnel
The reception staff is typically charged with maintaining patient files with vaccination information, including date administered, along with the production lot serial number and expiration date of the vaccine. Reception personnel are also responsible for contacting clients and scheduling follow-up appointments for booster series and yearly vaccinations in advance as directed by the prescribing veterinarian. Non-clinical staff should understand the potential life-threatening and minor adverse events that can occur following vaccination that require veterinary assistance.
Client Education

Pet owner clients are an essential member of a cat’s healthcare team. Although clients can be instrumental in helping improve healthcare for their cats, the Task Force recommends that vaccination be performed by a veterinarian. Vaccination is a medical procedure. Vaccines are available through sources other than a veterinarian, but they may not protect a cat against disease unless properly stored, handled, and administered. The principles of feline vaccination outlined in the box below represent a basic client education overview for cat owners. To help educate clients about vaccine and general health issues, both AAHA and the AAFP have handouts available to members and non-members. Additionally, more extensive information is available at aaha.org/felinevaccination and catvets.com/vaccination.

Summary

Vaccination protocols for cats should consist of recommended core vaccines and discretionary non-core vaccines as defined and listed in the guidelines. Vaccines in the latter category are given based on a risk-benefit assessment. Risk is determined by the patient’s life stage, lifestyle, clinical history, and health status and by environmental and epidemiologic risk factors. Although feline vaccination is universally practiced by primary care companion animal practices, there is no single protocol suitable for all feline patients. Rather, vaccination of cats should be patient-specific and guided by an individual risk-benefit assessment using the criteria listed in the guidelines. In the case of some vaccines, practitioners have a choice of different types of antigens, including those that are inactivated, attenuated, and in recombinant form. The patient’s clinical and vaccination status, such as the possible presence of maternally derived immunity or a history of adverse postvaccination reactions, are factors that may influence the choice of vaccine type.

Although most feline patients are household pets, practitioners should anticipate situations in which higher-risk cats are presented for vaccination, including those from shelter, cattery, feral, or foster care origins. Adverse postvaccination reactions unavoidably occur in a small percentage of cats. Because of their neoplastic etiology, FISSs continue to be the most serious, if infrequent, vaccine-associated adverse event. Detection of patterns in FISS incidence remains elusive, and their occurrence continues to be idiosyncratic. Advising clients in advance of the possibility of hypersensitivity or other reactions will help minimize their concerns. All members of the practice team, including clinical and non-clinical personnel, should have a well-informed understanding of the importance of vaccination of feline patients and be able to advise clients of the practice’s approach to an individualized vaccination plan. The vaccination visit is an ideal time for a client education dialog in which the clinical staff

Vaccination Talking Points for Clients

Vaccines help protect against specific infectious diseases. They stimulate the body’s immune system to recognize and fight an infection. Without vaccination, many cats would become seriously ill or die from preventable diseases. Some infections are more difficult to prevent using vaccination than others. For example, vaccination is very effective against feline panleukopenia infection but does not entirely protect against respiratory virus infections. However, cats vaccinated against respiratory tract infections generally have milder illness and are far less likely to die from their disease.

A veterinarian is the best person to evaluate a cat’s individual vaccination needs. Many factors need to be taken into consideration when deciding how often and for what diseases a feline patient needs to be vaccinated. These considerations include health status, age, and lifestyle of the cat; a vaccine’s duration of immunity; what diseases are prevalent in the area; and the severity of endemic diseases. Even cats living exclusively indoors require regular vaccination because they still may be exposed to diseases in many circumstances, such as when traveling or boarding, visiting a veterinary practice, interacting with other cats, or through viruses carried on the pet owner’s hands or clothing.

Veterinarian-administered vaccination is particularly important with respect to rabies. Rabies is a fatal but preventable disease that can be spread to humans by contact with saliva from an infected individual. If an unvaccinated cat is scratched or bitten by a wild animal, or if it bites a person, it should be quarantined or euthanized. In many US states, it is against the law for anyone other than a licensed veterinarian to administer a rabies vaccine. Rabies vaccination of cats is required by law in many but not all states. Ontario is the only Canadian province that requires rabies vaccination of cats. Even in areas where it is not required, feline rabies vaccination is still recommended (i.e., it is a core vaccine).

Severe vaccine reactions are rare. Veterinarians should convey the appropriate risk-benefit analysis of any vaccination. Cats may experience mild, short-lived reactions (malaise) such as poor appetite, lethargy, and fever that will resolve without treatment. Clients should seek immediate veterinary attention if their cat begins vomiting or scratching, develops bumps (hives) or facial swelling, or has difficulty breathing within a few hours of being vaccinated. The client and veterinary practice team have the same goal: to provide the best possible care for the pet.
their use in the publication was obtained from the people involved. The Task Force gratefully acknowledges the contribution of Mark Dana of Scientific Communications Services, LLC, and the Kanara Consulting Group, LLC, in the preparation of the guidelines manuscript.

CONFLICT OF INTEREST
Amy E. S. Stone has received speaking fees from Boehringer Ingelheim Animal Health USA Inc. Jane Sykes receives honoraria and research funding from Boehringer Ingelheim Animal Health USA Inc., Elanco Animal Health, IDEXX Laboratories Inc., and Merck Animal Health. Ernest P. Petersen was a stockholder of Phoenix Central Laboratory prior to its sale to Zoetis Petcare (after these guidelines were written) but was not employed at the lab nor on the Board of Governors, and was not involved in the sale. The other members of the Task Force have no conflicts of interest to declare.

FUNDING
Boehringer Ingelheim Animal Health USA Inc., Elanco Animal Health, Merck Animal Health, and Zoetis Petcare supported the development of the 2020 AAHA/AAFP Feline Vaccination Guidelines and resources through an educational grant to AAHA.

ETHICAL APPROVAL
This work did not involve the use of animals and, therefore, ethical approval was not necessarily required.

INFORMED CONSENT
This work did not involve the use of animals and, therefore, informed consent was not required. For any animals individually identifiable within this publication, informed consent (either verbal or written) for their use in the publication was obtained from the people involved.
